Abstract Glycomacropeptide (GMP) is a C-terminal part (f 106–169) of kappa-casein which is released in whey during cheese making by the action of chymosin. GMP being a biologically active component has gained much attention in the past decade. It also has unique chemical and functional properties. Many of the biological properties have been ascribed to the carbohydrate moieties attached to the peptide. The unique set of amino acids in GMP makes it a sought-after ingredient with nutraceutical properties. Besides its biological activity, GMP has several interesting techno-functional properties such as wide pH range solubility, emulsifying properties as well as foaming abilities which are shown to be promising for applications in food and nutrition industry. These properties of GMP have given new dimension for the profitable utilization of cheese whey to the dairy industry. A number of protocols for isolation of GMP from cheese whey have been reported. Moreover, its role in detection of sweet/rennet whey adulteration in milk and milk products has also attracted attention of various researchers, and many GMP-specific analytical methods have been proposed. This review discusses the chemico-functional properties of GMP and its role in the detection methods for checking cheese or sweet whey adulteration in milk. Recent concepts used in the isolation of GMP from cheese whey have also been discussed.

糖巨肽的化学和功能特性以及在检测干酪制作过程中掺假乳清的作用: 综述

摘要: 糖巨肽 (GMP) 是由 κ -酪蛋白的 C-末端部分 (f106-69) 构成的一种多肽, 是在凝乳酶的作用下从干酪制作过程中的乳清中释放出来。过去十年来, 糖巨肽作为一种生物活性成分, 引起了人们广泛的关注。它有其独特的化学和功能特性。GMP 的大多数生物特性应归因于与肽连接的糖基。GMP 中独特的氨基酸组成使它作为保健食品很受欢迎。GMP 除了具有生物活性外, 它还具有使人们感兴趣的加工特性, 如较广 pH 范围的溶解性、乳化性和起泡性, 这些特性使 GMP 在食品和营养方面有较广阔的应用前景。GMP 的这些特性给人们一种全新的思维, 那就是将干酪乳清合理的运用于乳制品工业中。很多关于从干酪乳清中分离 GMP 的实验方案和计划被报道。然而, GMP 在检测奶中甜乳清/凝乳乳清掺假方面的作用也引起了很多研究工作者的广泛关注, 提出了很多分析 GMP 的具体方法。本综述讨论了 GMP 的化学和功能特性以及在干酪和甜乳清掺假中的作用, 探讨了近期从干酪乳清中分离 GMP 的新的想法。

1 Introduction

In the middle of the twentieth century, scientists first found evidence about the presence of protein bound sialic acid in milk (György et al. 1954) while working on a variant of *Lactobacillus bifidus*. They observed that human and cow milk contain some bifido-factor which is not destroyed or altered in its activity even by autoclaving, although the ash was found to be inactive. However, it was the pioneering work of French workers (Delfour et al. 1965) who for the first time established that milk contains a sialic acid bound protein called kappa-casein (κ -CN). They also reported that glycomacropeptide (GMP), a sialic acid rich peptide, is formed by the cleavage of κ -CN between Phe₁₀₅-Met₁₀₆ by the action of rennet (chymosin) during the manufacture of cheese. It took many more years when GMP was taken as a new product opportunity. The GMP preparations until then were not pure enough to replace synthetic amino acid mixtures in the management of phenylketonuria and severe liver disease (Marshall 1991). Although GMP is released from κ -CN during cheese making by the action of rennet, smaller concentrations of GMP also exist in bovine milk. However, GMP released from casein is almost ten times higher than free GMP in mature milk (Furlanetti and Prata 2003). GMP constitutes 20–25% of total proteins in whey products viz., whey powder, whey protein isolates (WPI), whey protein concentrates (WPC) etc., manufactured from cheese whey (Fariás et al. 2010). It is recognized as a bioactive peptide and is thought to be an ingredient with a potential use in functional foods, and thus great interest has been generated for its isolation. The composition of GMP is variable and depends on the particular whey source and the fractionation technology employed in its isolation (Martín-Diana et al. 2006). Earlier, attempts were mainly made to review the isolation and biological

Fig. 1 Primary structure of bovine GMP variant A. The enclosed amino acids represent the sites corresponding to B variant (Eigel et al. 1984)

properties of GMP (Brody 2000; El-Salam et al. 1996; Thomä-Worringer et al. 2006). This article aims to discuss the chemical and functional properties of GMP and its role in the detection methods for checking cheese whey adulteration in milk and milk products. Some of the recent concepts used for the isolation of GMP from cheese whey are also discussed.

2 Chemical properties of GMP

GMP is significantly rich in the amino acids Pro, Glu, Ser, and Thr but depleted in Trp, Tyr, Phe, and Cys (Fig. 1). Of the three branched chain amino acids viz., Leu, Ile, and Val, GMP is rich in Ile and Val. The true 3D structure of GMP could not be established as crystallization has not been possible and a theoretical model has been suggested (Kreuz et al. 2009b). It has been predicted that GMP is a random coil or intrinsically disordered peptide without a defined secondary or tertiary structure and there is change in the conformation with change of ionic strength, pH, and presence of other molecules. These authors have predicted the 3D structure of GMP through protein modeling and have shown that a large part of the peptide has a strong negative charge, while there are three small positively charged domains at the N terminus. They also reported that at pH 7.0, the grand average of hydropathicity has a value of -0.322 , characterizing the peptide as more hydrophilic than hydrophobic. This value should be significantly decreased (more hydrophilic) in the case of glycosylated GMP due to the sialic acid residues.

2.1 Glycosylation

The carbohydrates are attached to κ -CN at Thr₁₃₁, 133, 135, 142 and Ser₁₄₁ positions through *O*-glycosylation linkages (Eigel et al. 1984). These positions are located more or less in the middle of the peptide backbone. The heterogeneous carbohydrate chains are the unique characteristics of GMP, not found in the remaining part (1 to 105) of κ -CN. Each of the GMP fractions with different carbohydrate chains might be responsible for different biological functions (Li and Mine 2004). The distribution of monosaccharide, disaccharide, trisaccharide (straight and branched), and tetrasaccharide chains is 0.8%, 6.3%, 18.4%, 18.5%, and 56.0%, respectively, as determined by HPLC (Saito et al. 1991). Mollé and Léonil (1995) using electrospray-ionization mass spectrometry (ESI-MS) found that out of five potential glycosylation sites, a

maximum of three are substituted with highly glycosylated carbohydrate chains which may contain up to six *N*-acetyl neuraminic acid (NeuNAc) residues per molecule. GMP is particularly rich in sialic acids which are substituted neuraminic acid derivatives, and the main representative forms of sialic acid are NeuNAc and *N*-glycolylneuraminic acid (Salcedo et al. 2011). The majority of the carbohydrate chains contain NeuNAc as a terminal residue α 2–3 or α 2–6 linked to GalNAc or Gal, respectively (Cherkaoui et al. 1997). Commercially available GMP with 78–83.7% protein content contains 7–9% of sialic acid (Arla Food Ingredients and Davisco Foods International, Inc.). Sialic acid offers one route of determining GMP concentration in a protein mixture. This is achieved by its reaction with certain compound leading to the formation of chromophore/fluorescent derivative which can be quantified (Neelima et al. 2012). On the basis of glycosylation, GMP can be classified into two major fractions: the glycosylated and phosphorylated glyco-peptide (gGMP), and the non-glycosylated but phosphorylated aglyco-peptide (aGMP) (Kreuz et al. 2009b). Fourteen glycosylated forms of GMP have been identified (Mollé and Léonil 1995) and gGMP form of GMP represent about 50% of the total GMP (Mollé and Léonil 2005). Heating of the milk or whey prior to isolation of GMP has an influence on the extent of glycosylation in isolated GMP; more severe heating produces GMP with less glycosylation (Taylor and Woonton 2009). Many of the biological and functional properties of GMP have been attributed to sialic acids (Fernando and Woonton 2010), but others have been linked to peptide part and still others are due to both peptide as well as glycan part (Table 1). Due to heterogeneity of GMP (because of glycosylation), GMP does not separate as a single peak in RP-HPLC, and this creates a problem in interpretation of cheese whey detection methods which are based on HPLC.

2.2 Isoelectric point (pI)

GMP is an acidic peptide with pI of around 4, highly soluble and heat stable (Thomä et al. 2006). This relatively acidic pI is related to the high amount of acidic amino acid side chains (Glu and Asp). GMP does not have a single pI because of heterogeneity in glycosylation and phosphorylation (Cherkaoui et al. 1997; Kreuß et al. 2008; Lieske et al. 2004; Nakano and Ozimek 2002; Silva-Hernandez et al. 2002). Using anion exchange chromatography, it was suggested that all sialylated GMP had an apparent pI < 3.8 (Nakano and Ozimek 2000b). The pI of 64 amino acids is around 4, but the sialate and phosphate have relatively low pK_a values of 2.6 and 2.0, respectively. The pI of GMP depends upon sialic acid and phosphate content present in it. Using laser Doppler electrophoresis and zeta potential measurement data, the pI of gGMP and aGMP was found to be 3.15 and 4.15, respectively (Kreuß et al. 2009b). GMP contains two Asp, seven or eight Glu (depending on genetic variants), one phosphorylated Ser, and three Lys residues. Below the pI, GMP molecules lose the negative charge of the Glu and Asp residues, carboxyl group at the C terminus, and the sialic acid residues. The positive charge of GMP below its pI is because of the Lys residue and the positively charged N terminus, while all Glu and Asp residues are protonated (Fariás et al. 2010; Kreuß et al. 2009b). The variation in the pI of GMP among aGMP and gGMP leads to multiple peaks which may affect the interpretation of the result in capillary electrophoresis (CE)-based cheese whey detection methods. Difference in pI of gGMP and aGMP has been exploited for the selective isolation of gGMP from commercial GMP preparations (Kreuß and Kulozik 2009).

2.3 Molecular weight

Using liquid chromatographic ESI-MS, the aGMP form of GMP was observed to have a molecular mass between 6,755 and 6,787 Da depending on the genetic variant of κ -CN from which it was derived. The average molecular mass of total gGMP is about 7,500 Da with the highest mass of up to 9,631 corresponding to highly glycosylated form (Mollé and Léonil 1995, 2005). It has also been suggested that the mass ratio between aGMP and the state of maximum glycosylation of gGMP differs from 7,000 Da to 11,000 Da with 36.4% overall molecular mass contribution of glycans (Kreuß et al. 2009b). In literature, often the molecular weight of GMP is given two to three times greater than the theoretical one which is caused by the association of monomers to form aggregates. The behavior of GMP on SDS-PAGE indicates that peptide is in polymeric form with molecular weight ranging from 14 to 30 kDa (Fariás et al. 2010; Galindo-Amaya et al. 2006). It has been suggested that GMP has the ability of associating and dissociating under selected pH conditions. Earlier, it was proposed that the 9-kDa monomer of GMP is obtained at pH \leq 4 and the polymer of 45–50-kDa GMP is obtained at pH higher than 4 (Kawasaki et al. 1993b). On the contrary, Nakano and Ozimek (1998) used gel chromatography over Sephacryl S-200 gel and suggested that GMP is an aggregate of three monomers, and the molecular weight was not affected by changes in pH.

It has also been suggested that pH-dependent interactions between GMP molecules seem to take place within the κ -CN micelles which influence the resulting GMP product arising from enzymatic cleavage. GMP units in κ -CN appear to associate

reversibly depending on pH, whereas the GMP monomers do not tend to associate once they have been formed. The apparent aggregation of GMP is not solely influenced by the actual pH and strong hydrophobic contacts have been hypothesized which hold together polymeric forms. The tetrameric form of GMP is more hydrophobic than the dimeric and monomeric forms (Mikkelsen et al. 2005). Using dynamic light scattering technique, recent studies indicate that pH is very important in controlling GMP aggregation. GMP undergoes a pH-dependent self-assembly at room temperature. At pH below 4.5, GMP self-aggregates due to hydrophobic interactions ultimately leading to gelation. The size of aggregate and gelation further increases on decreasing the pH and in this role of sialic acid which retains a negative charge at pH 2.2 is important. It has been concluded that self-assembled structures formed at room temperature are partially pH-reversible, but hydrophobically formed dimers appear to be resistant to pH changes once formed (Farias et al. 2010; Martinez et al. 2012). Self-aggregation of GMP can create problem in its identification and its use as a marker peptide in cheese whey adulteration detection methods which are based on electrophoresis and Western blot. Self-aggregation of GMP may be of interest to protein chemists as the phenomenon is not still fully understood. The separation of individual GMP monomer and its visualization on SDS–PAGE has not yet been achieved. More research efforts are required to delineate the conditions under which GMP exists in monomeric form. This would also pave the way for the development of a simple method for detection of cheese whey adulteration in milk as presence of a 7-kDa (monomeric form of GMP) band in electrophoretic separation of whey obtained after precipitation of casein at 4.6 would ascertain the presence of GMP in suspected milk sample.

2.4 UV characteristics

GMP lacks aromatic amino acids (Phe, Trp, and Tyr) and, therefore, it has no absorption at 280 nm. It is known that GMP is only detected in the range of 205–226 nm, and differences in the absorption at 210 and 280 nm are frequently used to characterize GMP (Oliva et al. 2002); this has been the most commonly used tool to perceive the presence of GMP during HPLC.

3 Isolation of GMP

Developments in the knowledge about GMP during the last four decades, comprising its isolation techniques, biological properties, and functional properties used/discovered by different researchers, are compiled in Table 2. Isolation of GMP from cheese whey has been attempted by various techniques such as trichloroacetic acid (TCA) precipitation (Lieske and Konrad 1996), ethyl alcohol precipitation (Saito et al. 1991), ultrafiltration (UF) (Kawasaki et al. 1993b), and chromatographic techniques such as gel chromatography (Nakano and Ozimek 2000a), affinity chromatography (AC) (Saito et al. 1991), hydrophobic interaction chromatography (HIC) (Silva-Hernandez et al. 2002), and ion exchange chromatography (IEC) (Tanimoto et al. 1992). Most of the time, it is the combination of different techniques which work best, and these various combinations used for GMP isolation have been categorized

Table 2 Chronological order of isolation, biological properties, and functional properties used by various workers for GMP

Year	Isolation techniques	Biological properties	Functional properties
1970–1980	– IEC (Burton and Skudder 1987)	– Bifido-factor (György et al. 1954)– Inhibition of gastric secretion (Vasilevskaya et al. 1977)	– Gelation (Burton and Skudder 1987)
1980–1990	– Gel filtration, IEC, and AC (Morr and Seo 1988)	– Anti-cariogenic (Neesser et al. 1988)– Modulation of immune system (Otani and Monnai 1993; Otani et al. 1992)	– Emulsification (Chobert et al. 1989)
1990–2000	– Alcohol precipitation and AC (Saito et al. 1991)– UF (Kawasaki et al. 1993b)– TCA precipitation (Lieske and Konrad 1996)– IEC (Tanimoto et al. 1992)– Gel chromatography (Nakano and Ozimek 2000a)	– Inhibition of cholera toxin binding (Kawasaki et al. 1992)	– Overrun (Marshall 1991)
2000–2010	– HIC (Silva-Hernandez et al. 2002)– Enzyme cross-linking (Tolkach and Kulozik 2005)– MAC (Kreuß and Kulozik 2009)– ATPS (da Silva et al. 2009)	– Prevention of intestinal infection (Nakajima et al. 2005)– Nutritional management of phenylketonuria (LaClair et al. 2009)	– Interfacial behavior studies (Kreuß et al. 2009b)– Emulsification (Martin-Diana et al. 2005)– Gelation (Farias et al. 2010)
2010 onwards	– UF (Robitaille et al. 2012)	– Antibacterial and probacterial activity of pepsin-treated GMP (Robitaille et al. 2012)	– Foaming properties of GMP- β -lg mixed systems (Martinez et al. 2012)

IEC ion exchange chromatography, *AC* affinity chromatography, *UF* ultrafiltration, *TCA* trichloroacetic acid, *HIC* hydrophobic interaction chromatography, *ATPS* aqueous two-phase systems, *MAC* membrane adsorption chromatography

(Tullio et al. 2007) into three different approaches: (a) selective precipitation using heating/alcohol/acetic acid/TCA, (b) membrane filtration using UF/microfiltration (MF)/dialysis/reverse osmosis/electrodialysis, and (c) selective adsorption using IEC/HIC/AC.

In a comparative study (Li and Mine 2004) based on the chromatographic profile of GMP isolated by three methods (TCA fractionation, ethanol precipitation, and UF) from WPI, UF was found to be the most effective in recovering GMP. The method is based on the concept given earlier by Kawasaki et al. (1993b) that at pH 3.5 GMP permeates through UF membranes with a molecular weight cut-off (MWCO) ranging from 20 to 50 kDa and majority of whey proteins such as β -lactoglobulin, α -lactalbumin, immunoglobulins, and bovine serum albumin being held back. The pH of permeate is then adjusted to 7.0 where GMP forms non-covalent linked polymers and is then concentrated using the same membrane. The recovery rate of GMP using

this particular technique was around 34% with more than 80% GMP in the glycosylated form. The authors recommended a combination of UF and anion exchange chromatography as a suitable and practical approach on an industrial scale. The less recovery obtained by these workers makes the method unsuitable for commercial purpose. The formation of self-assembled aggregates of GMP at low pH has been reported in some of the recent studies (Martinez et al. 2009; Farías et al. 2010), and it is possible that during UF most of GMP remains with the retentate at pH 3.5 as GMP is already in aggregated or dimer form.

Using an altogether different approach, Tolkach and Kulozik (2005) isolated GMP by enzymatic cross-linking technique. This approach involves pre-treatment of WPC with the enzyme transglutaminase (Tgase). GMP can be cross-linked by Tgase due to the presence of two glutamic acid and three lysine residues in its primary structure. Further, it has been stressed that the presence of sugar residues in GMP provides its hydrophilic character which facilitates the enzyme action. On the other hand, native whey proteins show much less sensitivity to be cross-linked by the Tgase due to their globular structure with relatively little exposure of the protein chain to the exterior. The GMP aggregates are then removed by MF or diafiltration (DF). However, the procedure only separates native whey proteins from GMP and may not be applicable to heated whey. As cross-linking of other milk proteins by Tgase changes its functional properties (Bönisch et al. 2007; Czernicka et al. 2009), it is expected that functional properties of GMP isolated by Tgase would also change. Further investigation in this regards is required.

The *pI* of GMP is around 4.0 while *pI* of other major whey proteins is above 4.8 (Fox and McSweeney 1998). This difference in *pI* has been used in the pilot-scale isolation of GMP using anion-exchange membrane adsorption chromatography (MAC) (Kreuß and Kulozik 2009). The chemistry and binding conditions were given earlier by the same group (Kreuß et al. 2008), who developed and optimized a process for separation of glycosylated and non-glycosylated fractions of the macropeptide using MAC. The module consisted of a spiral packed cellulose-based strong anionic membrane coiled around a solid core. The fouling was decreased by prior MF of whey or by increasing the temperature of the adsorption process. The process development further included a desalting and concentration step, which was performed by a 10-kDa MWCO UF/DF. The efficiency of the UF was strongly influenced by the pH of the solutions and showed best performance at pH 4.1 for the eluate. Using this technique, 91% purity of GMP (glycosylated form) could be achieved. Fouling of the membrane was found to be a major issue in this isolation procedure. This approach allows selective isolation of glycosylated form of GMP from commercial GMP preparation and may appeal to manufacturers of GMP for its further fractionation and product diversification.

The aqueous two-phase systems (ATPS) have been widely used in biochemistry, cell biology, and biotechnology (Oliveira et al. 2002). An ATPS is formed when two water-soluble polymers, such as polyethylene glycol (PEG) and dextran, or a polymer and a salt are dissolved in water beyond a critical concentration at which two immiscible phases are formed. Partitioning of GMP using ATPS has been attempted by da Silva et al. (2009). In their study, the use of PEG and sodium citrate as ATPS for the partitioning of GMP has been proposed. The parameters (PEG molar mass, tie line length, pH, NaCl concentration, and temperature), which affect the partitioning

behavior of the protein, were also investigated. It was verified that larger tie line lengths and higher temperatures favor GMP partition to the PEG phase. Furthermore, PEG molar mass and concentration had a slight effect on GMP partition. The increase in the molar mass of PEG induced a reduction of the protein solubility in the top PEG-rich phase. A protein recovery higher than 85% was obtained in the top phase (PEG-rich phase) of these systems, demonstrating its suitability as a starting point for the isolation of GMP. Later, PEG/ammonium sulfate ATPS was also used to separate GMP (Wu et al. 2012). It was found that the molecular weight of PEG and concentration of both the phases influence the partitioning of GMP. These experiments showed that 18% (w/w) PEG6000 and 15% (w/w) ammonium sulfate were the optimum system in which the protein recovery was around 70%. The removal of polymers from isolated GMP requires another step of chromatography like size-exclusion chromatography which makes the isolation procedure tedious.

All the aforementioned novel approaches for the isolation of GMP from cheese whey are in their preliminary stages. The earlier literature indicates that combination of ion-exchange chromatography and UF provides the best result in terms of recovery as well as for scale-up operations. The manufacturer of GMP would be interested in those approaches which allow the use of the spent whey for other food applications. Since the *pI* of GMP varies with extent of glycosylation, more research may be required to elaborate the optimum conditions of pH, type of exchanger, elution buffer, temperature conditions, etc. to recover maximum GMP from cheese whey.

4 Functional properties of GMP

The functional properties of GMP which have received attention include its emulsification, foaming, and gel formation ability. Like the biological properties, functional properties are equally affected by the glycosylation of GMP. It is worth mentioning here that the solubility of GMP in aqueous medium is proportional to its glycosylation (Taylor and Woonton 2009).

4.1 Emulsification and foaming properties

Emulsifying and foaming properties are among the most important functional properties of milk proteins, and the characteristics of most dairy products depend on how the milk protein fraction is organized at fat–serum and air–serum interfaces (Dickinson 2003). GMP present in WPC also contributes to the emulsification (Chobert et al. 1989). When compared with WPC, the emulsifying activity index of GMP was shown to be significantly lower ($36 \text{ m}^2 \text{ g}^{-1}$ for GMP and $185 \text{ m}^2 \text{ g}^{-1}$ for WPC), but GMP had more stable emulsifying activity index with respect to pH than WPC, suggesting the possible utilization of GMP as emulsifier in foods which undergo large pH variations during processing, i.e., fermented dairy products (Martin-Diana et al. 2005). The glycosylated and non-glycosylated GMP fractions exhibit different emulsification properties as glycan moiety significantly affect the surface activity (Fig. 2a). In a study by Kreuß et al. (2009b), aGMP showed a higher emulsifying activity index of $150.7 \text{ m}^2 \text{ g}^{-1}$ while gGMP achieved a lower value of $98.5 \text{ m}^2 \text{ g}^{-1}$. Also, the stability of emulsions was 1.4 times higher for aGMP as compared to gGMP. The pH of the emulsion greatly

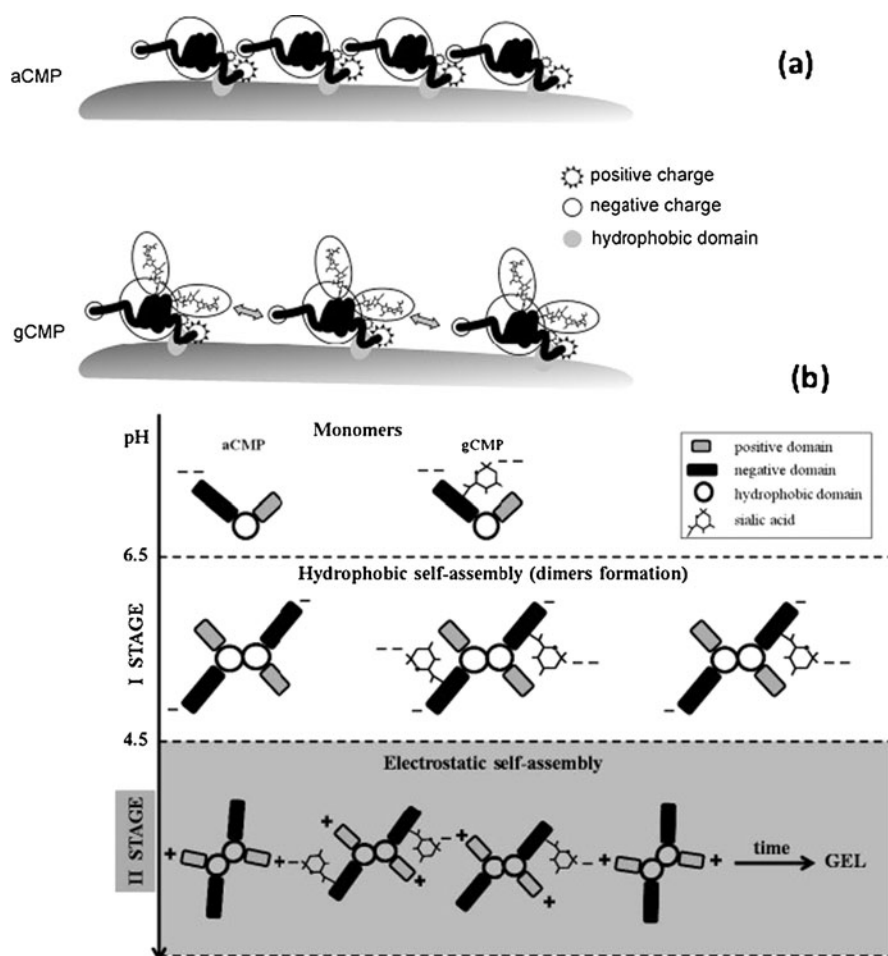

Fig. 2 Role of glycosylation on GMP self-assembly and foaming property **a** adsorption of aGMP and gGMP at hydrophobic/hydrophilic interface. aGMP can make a stable layer at the interface while in gGMP glycan chains create repulsive forces; **b** a model to explain the pH-dependent self-assembly of GMP. Below pH 4.5, glycan chains provide a negative charge for gel formation. Adapted from Kreuß et al. (2009b) and Fariás et al. (2010). (Figures used with permission)

influences both the formation and stability of the emulsions formed by GMP. At the oil–water interface, above the pI there is an average stabilized adsorption of peptide with negative repulsion between individual oil droplets. At the pI , due to lack of repulsive forces, the oil droplets coalesce. Below the pI , there is repulsive positive charge which stabilizes the oil droplets.

The hydrophilic nature of GMP reduces the emulsifying activity as compared to native amphipathic κ -CN. Attempts have been made to modify the emulsification activity of GMP by conjugating it with other molecules such as lactose (Moreno et al. 2002) and fatty acids (Wong et al. 2006). Lactose has been conjugated with GMP using Maillard reaction chemistry and such conjugation has been reported to increase the emulsifying activity without significantly reducing the macropeptide solubility (Moreno et al. 2002). Long-chain fatty acids have been conjugated to GMP

using lipophilization reaction involving *N*-hydroxysuccinimide fatty esters (Wong et al. 2006). The modified GMP has been shown to have improved functionality as a surfactant with enhanced antibacterial activity towards gram-negative bacteria.

Like emulsification, foaming ability also depends upon glycosylation. GMP is a good foam-building peptide as it efficiently reduces surface tension and assures high gas content during foaming but makes unstable foams compared to foams made with WPI (Thomä-Worringer et al. 2007). Moreover, 10% of whole GMP solution was found to give a higher overrun, but inferior foam stability compared with egg white (Marshall 1991). Kreuß et al. (2009a) studied both gGMP and aGMP for their foaming properties in terms of overrun, foam rigidity, and drainage at pH 6.0. They found that aGMP-stabilized foams show significantly higher foam rigidity and stability than foams stabilized with gGMP, whereas both fractions yield a high foaming ability with overruns of around 600%. They hypothesized that a combination of steric and electrostatic repulsion of the glycan is responsible for this difference.

4.2 Gel formation

Gel is an intermediary form between solid and liquid. Food processing and the development of new products require ingredients such as the gelling agents, which build up a structural matrix that supplies food its desirable texture. It has been proposed that GMP has the capability to form gel and this is because of strong hydrophobic links between the monomer molecules. At neutral pH, most of the hydrophobic domains (containing Val, Pro, Ile, Ala, and Met) cannot interact as these are masked by strong charge density of negatively charged amino acids (Glu and Asp). Above pH 6.5, Glu and Asp get deprotonated which produces a strong negative shield thereby preventing GMP self-association. Below pH 6.5, the protonation of these acidic amino acids increases which decreases their shielding effect, allowing the hydrophobic domains to interact causing self-assembly. GMP solutions (3–10%, w/w) below pH 4.5 show time-dependent self-assembly at room temperature leading to gelation. A GMP self-assembly model (Fig. 2b) has been proposed according to which self-assembly occurs in two different stages—a first stage of hydrophobic interaction to form dimers and in the second stage the dimers further interact through electrostatic bonds to form gels. In the second stage, the presence of charged glycosidic side chain plays an important role as it contributes to the negative charge at low pH (Farias et al. 2010).

The effect of added WPC and GMP on the rheological and structural properties of fermented milk prepared from goat milk has been studied. The addition was found to enhance elasticity versus viscosity of the gel, thereby favoring the use of GMP in fermented milks leading to the formation of a more orderly and structured gel compared to using WPC (Martin-Diana et al. 2004).

5 Role of GMP in detection of cheese whey adulteration in milk

Adulteration of milk continues to represent a major concern not only for consumers but for manufacturers also, as it affects the quality of dairy products. Adulteration of

milk by adding cheese whey is economically attractive because cheese whey cost is four to five times lower than milk and it does not adversely affect the sensory perception of product. Furthermore, because of its high biological oxygen demand, disposal of cheese/rennet whey is a problem, and is often used for adulteration of milk and milk products (Chávez et al. 2008; Martín-Hernández et al. 2009). Various methods for detection of cheese whey in milk have been reported. The developed methods can broadly be categorized into two different groups. One group consists of methods based on the compositional difference between cheese/rennet whey and milk (non-GMP-based methods). These include the determination of the ratio of casein and whey protein using derivative spectroscopy (Miralles et al. 2000), electrophoretic analysis (De Souza et al. 2000), by analyzing casein bound phosphorus index (Wolfschoon-Pombo and Furtado 1989) and the quantification of cysteine and cystine ratio through polarography (Mrowetz and Klostermeyer 1976). The other group includes methods which are mainly based on the presence of GMP in the suspected samples and are known as GMP-based methods. Although free GMP is also present in mature milk, as mentioned before, but as the concentration is very small, it becomes an important marker of adulteration of cheese whey in milk. The techniques used for the detection of cheese whey in milk based on GMP are presented in Table 3 and explained as follows:

5.1 Colorimetric methods

In one approach, reaction of sialic acid with thiobarbituric acid, as suggested by Warren (1959), has been exploited for detection of cheese whey in milk. In a method proposed by Koning et al. (1966), precipitation of milk proteins has been done by TCA followed by GMP precipitation by phosphotungstic acid. In the GMP precipitates, sialic acid is estimated by TBA assay which is then correlated to the presence of GMP. This method was further used by Josephson et al. (1980) to detect cheese whey replacement for non-fat milk solids in ice milk mixes. Samples with GMP precipitate (per 100 g mix) having a dry weight above 55 mg were said to be suspected.

Nakano and Ozimek (1999) reported that the estimation/detection of sialic acid in the reaction mixture after the removal of interfering κ -CN can provide indication of the presence of cheese whey in suspected milk or milk product samples. Fukuda et al. (1994) adapted a technique described earlier (Yao et al. 1989) wherein acidic ninhydrin was used as a chromophore for the determination of the concentration of sialic acid in sialoglycoprotein. In the same year, Fukuda (1994) proposed a spectrophotometric (470 nm) acidic ninhydrin method for quantitative determination of sialic acid, free or linked to the glycoprotein in fluid milk and rennet whey. This method required addition of TCA (final concentration 12%) to remove the interfering proteins followed by precipitation of GMP using phosphotungstic acid. Alternatively, milk proteins can also be removed by 8% TCA followed by GMP precipitation with 14% TCA (Rao et al. 2012). The precipitates on heating with acid ninhydrin reagent produced a yellow color, the absorbance of which was measured spectrophotometrically. Fukuda et al. (1996) proposed $A_{470} \leq 0.300$ (≤ 5.14 μg free sialic acid per liter in milk samples) for the negative category, A_{470} between 0.300 and 0.600 (5.14 and 10.64 μg free sialic acid per liter of milk) for suspect, and $A_{470} > 0.600$ (> 10.64 μg

Table 3 Comparison of various GMP-based detection methods

Methods	TCA pre-treatment	Limit of detection	Merits	Demerits	References
Colorimetric method	✓	5–10% ^a	No expensive equipment required	Less specificity, low detection limit	Koning et al. (1966); Fukuda (1994); Fukuda et al. (1994, 1996, 2004); Nakano and Ozimek (1999)
Fluorimetric method	✓	5% ^a	Specific to sialic acid	Expensive equipment	Neelima et al. (2012)
Chromatographic method	–	–	Specificity, convenience	Co-eluting compounds may lead to false-positive results	Kawakami et al. (1992)
Immunological methods					
<i>ELISA</i>	✓	0.047% ^a	Easy to use, short assay time, rapid analysis of large number of samples	Even traces of κ -CN can lead to false-positive results	Chávez et al. (2012)
<i>Western Blot</i>	✓	0.5% ^a	High specificity of immunoblot	Even traces of κ -CN can lead to false-positive results, long procedure time, skilled personnel required	Chávez et al. (2008)
<i>Immunochromatographic strips</i>	✓	1% ^a	Low cost, suitable for routine analysis	Even traces of κ -CN can lead to false-positive results	Martín-Hernández et al. (2009)
SDS-PAGE	✓	1% ^a	Gives fairly accurate results	Long procedure time, low specificity, skilled personnel required	Galindo-Amaya et al. (2006)
Capillary electrophoresis	–	–	High efficiency and resolution, low solvent consumption, short analysis time	Interference due to proteolysis in stored milk and difficulty in interpretation of results	Recio et al. (2000)
Biosensors	✓	1% ^b	Specific, robust analytical tool	Expensive equipment required	Haasnoot et al. (2006)

^a Limit of detection is expressed as presence of cheese whey in milk (v/v)^b Limit of detection is expressed as presence of whey solids in milk (w/w)

free sialic acid per liter in milk samples) for positive category of milk samples. Prata (2002) also confirmed that acidic ninhydrin reaction method can be efficiently used in fraud detection of whey addition to milk. In April 2003, the technique of acidic ninhydrin reaction for the quantitative determination of sialic acid was approved by the Brazilian Ministry of Agriculture as an Official method (Ministry of Agriculture Livestock and Food Supply of Brazil 2003). Later on, in their study, Fukuda et al. (2004) compared the acidic ninhydrin spectrophotometric method with European Union recommended HPLC method (Official Journal of the European Communities L 037, 2001) and found good correlation in these two methods.

Although sialic acid determination methods have been claimed to be sensitive, it is worth mentioning that the colorimetric methods for the determination of sialic acid (both TBA as well as ninhydrin based) are not specific and interfering substances may alter the results. This is evident by the presence of high blank values reported by Fukuda et al. (2004). Later, Matsuno and Suzuki (2008) have developed a new fluorimetric method for the estimation of sialic acid in glycoproteins. This method involves periodate oxidation of sialic acid (both bound as well as unbound) to formaldehyde followed by its estimation by Hantzsch reaction wherein a fluorescent compound is formed. The method is claimed to be specific for sialic acid and has been applied for detection of adulteration of milk with cheese whey (Neelima et al. 2012). In this method, selective precipitation of GMP was done using TCA wherein its concentration in milk was first raised to 5% to precipitate milk proteins, especially κ -CN, followed by raising the TCA concentration to 14% to precipitate out GMP. In the precipitates, sialic acid was estimated using fluorimetric method and the fluorescence intensity was found to be linked to the level of sweet whey in adulterated milk samples. The method was found to detect the presence of 5% sweet whey in milk. As these methods are based on the presence of sialic acid in GMP, loss of sialic from GMP during sample processing can significantly affect the results.

5.2 SDS–PAGE

A SDS–PAGE-based method has been developed for the detection of GMP in milk after the selective precipitation of GMP from milk using TCA. Galindo-Amaya et al. (2006) have isolated GMP from milk and adulterated milk sample with sequential precipitation in TCA (8% and 16%), treatment with ethanol-ether, and re-suspension in Tris–HCl buffer. Precipitates were analyzed by SDS–PAGE and GMP was evidenced as a trimer of 20.8 kDa in samples of sweet whey, and mixtures of whey and milk (1%, 5%, 10%, and 50%), but absent in samples of acid whey and raw milk. The authors claim that the detection of GMP in milk using SDS–PAGE is a sensitive and specific method of detecting milk adulteration with whey, to levels as low as 1%. The experience in authors' laboratory suggests that the trimer of GMP and κ -CN move closely and usually it is difficult to distinguish between them.

5.3 Capillary electrophoresis

CE has been proven to be a useful technique in the analysis of proteins, peptides, and their glycoforms (Chen et al. 1991; Kakehi and Honda 1996; Righetti 1996). In CE, small amounts of fluids are injected into a separation channel by using plug injection.

Substances are separated based on their electrophoretic mobility, which is proportional to their charge to size in the interior of a small capillary filled with an electrolyte. Otte et al. (1995) have described a CE method for the separation of the major whey proteins using acidic and basic conditions. Under acidic conditions (70 mM phosphate, pH 2.5), a GMP peak was separated from the other whey proteins. Van Riel and Olieman (1995) employed the CE method for the detection of rennet whey solids in skim milk and buttermilk powder, based on the non-glycosylated A and B genetic variants of GMP. Later, Cherkaoui et al. (1997) validated a method for the analysis and quantitative determination of a GMP mixture. Commercially available GMP was used for method development and it was not applied to milk or whey samples. They used the 20-mM sodium citrate buffer at pH 3.5. At this pH, all GMP forms were anionic and the other whey proteins were cationic providing selectivity to the method. Recio et al. (1996, 2000) demonstrated the suitability of the CE method to identify GMP in liquid milk sample and observed the presence of detectable GMP in stored UHT milk samples incubated with psychrotrophs. The authors have observed that this might give rise to false-positive results when the presence of rennet whey is being investigated by CE. The CE-based method has not been used in the subsequent years as the result interpretation is difficult (due to fluctuation in migration) and the technique itself is technically demanding.

5.4 Chromatographic methods

HPLC using ion-exchange, gel permeation, hydrophobic interaction, and reverse-phase (RP) separations have become important techniques for separation and quantification of milk proteins as these combine versatility and short analysis time. Detection of GMP in cheese whey has been attempted by HPLC with a reasonable success. The work in this direction was initiated by Van Hooydonk and Olieman (1982) who described a gel permeation HPLC as a fast and sensitive method to monitor the action of chymosin in milk. Olieman and Bedem (1983) used this method to detect and estimate the presence of milk serum solids obtained by the action of the rennin in skimmed milk powder (SMP). The GMP detection by HPLC depends on the removal of the other proteins using TCA. To prevent interfering factors in the determination of GMP by chromatography, 8% TCA is considered as the best concentration at which the cheese whey proteins are virtually absent (Van Hooydonk and Olieman 1982). It has been reported that low concentrations of TCA result in removal of the whey proteins in low proportion, while high concentrations cause precipitation of larger amounts of GMP. Later on, Kawakami et al. (1992) described a method for determination of glycosylated and non-glycosylated GMP by size-exclusion chromatography using two coupled TSK gel G3000 PW columns and anion-exchange chromatography on a Mono Q HR 5/5 column without pre-treatment of samples with TCA. The superiority of the method described was to distinguish heterogeneous GMP by the variations in carbohydrate moiety and to determine GMP content without pre-treatment of milk samples with TCA. The concepts developed for all these methods were later on used for the development of European Union (EU) methods for the detection of frauds of addition of whey for the manufacture of dried milks.

Adulteration of SMP is particularly attractive as the EU subsidizes the public storage of SMP and the processing of these powders intended for animal feed. To be eligible for EU subsidy, milk powders must be prepared exclusively from skim milk and should not contain solids from whey. To combat subsidy fraud, the EU has imposed two-step methods (screening followed by confirmatory) for the detection of rennet whey in dried milks (Official Journal of the European Communities L 037, 2001). The initial screening method involved gel permeation chromatography for all samples, followed by a confirmation step using RP-HPLC. Both methods detect the presence of GMP in the sample. The screening method requires reconstitution of the SMP, removal of fat and proteins with TCA, followed by centrifugation. GMP is then determined in the supernatant by gel filtration HPLC using UV detection at 205 nm. The results are then required to be evaluated vis-à-vis results obtained for the samples by reference to standard samples consisting of SMP with or without the addition of a known percentage of whey powder. If the sample indicates the presence of GMP by the preliminary method, the results are further confirmed by a RP-HPLC procedure using UV-vis detection at 210 nm. The method could detect presence of 1% rennet whey solids in SMP. Ferreira and Oliveira (2003) have employed the RP-HPLC using polystyrenedivinylbenzene column which has excellent chemical and pH stability and is quite robust. The workers have employed pH 4.6 filtrate from the adulterated samples, and the sample was eluted using the gradient of two solvents. Solvent A was 0.1% trifluoroacetic acid (TFA) in water and solvent B was 95% acetonitrile–5% water–0.1% TFA. The eluate was monitored by a UV detector at 214 nm and enabled the separation of three peaks, two of which corresponded to the aGMP components of the two principal genetic variants (A and B), and were eluted after the less well-resolved gGMP components. GMP in samples was calculated from integrating and peak identification was carried out by comparison with commercially purified bovine whey protein standards.

5.5 Immunological methods

In these types of methods, antibodies are raised against GMP or κ -CN which is then used to develop various techniques to visualize antigen–antibody reaction. Although immunological methods are credited for their specificity, they give false-positive results if even a trace amount of κ -CN (from which GMP derives) is present in the sample. Some of these techniques are described below:

5.5.1 Enzyme-linked immunosorbent assay (ELISA)

An inhibition ELISA for the detection of bovine rennet whey solids in SMP and buttermilk powder has been developed (Bremer et al. 2008). The affinity purified monoclonal antibodies developed against bovine κ -CN which could recognize bovine GMP were used in this ELISA. The removal of κ -CN was achieved by precipitation of all milk proteins using TCA. The rennet whey content was determined in a neutralized TCA sample extract by binding of the soluble GMP to a peroxidase-labeled anti-bovine- κ -CN monoclonal antibody. For quantitative assay, calibration curves were constructed by analyzing SMP standards with different known concentrations of rennet whey (0–5.8%, w/w). The assay has a limit of detection of 0.1% (w/

w) rennet whey powder in SMP with high repeatability and reliability. Recently, a sandwich ELISA for the detection and quantification of whey in raw milk and milk products has been developed using a polyclonal rabbit anti-GMP antibody (Chávez et al. 2012). In the assay, 96-well microplates are coated overnight with rabbit anti-GMP antibodies. GMP in the TCA-treated sample is then conjugated to it followed by binding with biotinylated rabbit anti-GMP antibody. The complex is then made to react with HRP–avidin followed by addition of substrate. The method can detect presence of 0.047% of cheese whey in milk with quantification limit of 0.14% (v/v).

5.5.2 Western blot

Western blotting (protein blotting or immunoblotting) is a powerful and important procedure for the immunodetection of proteins post-electrophoresis, particularly proteins that are of low abundance. Chávez et al. (2008) have developed a Western blot protocol for the detection of GMP in adulterated milk samples. The method was developed using affinity purified specific polyclonal anti-GMP antibodies. When used in Western blot, these anti-GMP antibodies recognized two bands of 20.1 and 14 kDa for pure GMP. In cheese whey, one more band of molecular weight of 45 kDa was visualized. This phenomenon of recognition of different bands has been ascribed to the self-aggregation of GMP leading to the formation of dimers, trimers, tetramers, etc. (Galindo-Amaya et al. 2006). The authors have reported more abundance of GMP aggregates of 20.1 kDa than 14 or 45 kDa in pure GMP as well as in whey, indicating the higher amount of trimer form. They have finally recommended the presence of a GMP-specific band at 20.1 kDa as marker of adulteration. Sample preparation involves mixing of liquid samples with TCA to a final concentration of 8% in order to precipitate κ -CN which cross-react with GMP. The GMP was precipitated with 14% TCA and used for immunoblot after dissolving in buffer. This method can detect 0.5% (v/v) of liquid whey in milk in 4.5 h. The use of polyclonal antibodies instead of monoclonal antibodies is justified since different food processing techniques can affect their proteins or peptides, for example, by destroying specific epitopes.

5.5.3 Immunochromatographic strips

The lateral flow assay (LFA), also called the immunochromatographic assay or the strip assay, is a simple device intended to detect the presence (or absence) of a target analyte in the sample (matrix). This technique is based on an immunochromatographic procedure that utilizes antigen–antibody properties and enables rapid detection of the analyte. A LFA-based dipstick test has been developed for the fast detection of bovine rennet whey in liquid milk and milk powder (Martín-Hernández et al. 2009). The test is based on the binding of GMP by two different anti-bovine κ -CN monoclonal antibodies and has a visual detection limit of around 15 ng mL^{-1} for GMP and 1% (v/v) for rennet whey in milk using standards and spiked samples. The dipstick performance was evaluated in a collaborative trial using SMP and raw, pasteurized, and UHT milk. These researchers also demonstrated the suitability of the dipstick in comparison with gel permeation–high performance liquid chromatography and a colorimetric method by analyzing 60 raw milk samples collected from farms in Brazil. The dipstick results correlated well with the

HPLC results and were more reliable than those obtained with the colorimetric method. The dipstick test correctly identified all raw milk samples with rennet whey content above 4%. Since monoclonal antibodies were raised against κ -CN, the prior removal of κ -CN from the milk sample is necessary and this has been done by adding 20% TCA to a final concentration of 8%. The technique has been commercialized by Operon under the brand name Immunostick c-GMP. The method has been evaluated by Oancea (2009) and has found its applicability in unprocessed and processed milk, condensed milk, powdered milk, and dairy beverages of cappuccino, chocolate, banana, and strawberry flavors. For quantitative analysis, an immunochromatic reader was used.

5.6 Biosensors for detection of GMP

Haasnoot et al. (2006) have developed a surface plasmon resonance (SPR)-based biosensor for the detection of fraudulent addition of whey in milk and milk powder. The SPR method is based on optical measurement of refractive index changes associated with the binding of analyte molecules in a sample to biorecognize molecules immobilized on the SPR sensor. In their study, the authors have immobilized monoclonal antibodies raised against κ -casein onto the chip surface and the binding of GMP was measured using SPR. The authors have used Biacore biosensors (Biacore AB, Uppsala, Sweden) which have been proven to be robust analytical tools for the automated immunochemical detection of whey in milk and milk powder. However, the significant cost of the instruments is a disincentive for their wide application in food control laboratories. The authors have also proposed an alternative low-cost optical biosensor (Spreeta; Texas Instruments, Attleboro, MA, USA). Using this prototype biosensor, an inhibition immunoassay for bovine κ -CN was evaluated for the detection of bovine rennet whey powder in milk powder. Comparable sensitivities were obtained for Spreeta-based biosensor and a Biacore 3000 instrument. The method has been claimed to detect the presence of 1% bovine rennet whey powder in milk powder.

Although a number of approaches have been attempted to develop methods for the detection of cheese whey in milk using GMP as a marker, these methods have not been validated and are not in use with a few exceptions (ninhydrin and HPLC-based methods). Also, in the authors' laboratory different attempts have been made to develop a protocol for the detection of cheese whey in milk involving electrophoresis, Western blot using antibody and carbohydrate-based detection, and LFA (unpublished data). It has been experienced that the chances of getting false-positive results are greater with all these sensitive methods. It appears that native GMP in pure milk samples, as indicated earlier also by Furlanetti and Prata (2003), may be the cause of high false-positive data. This warrants more research to establish the presence of native GMP in pure milk which may appear in milk due to incomplete synthesis of κ -CN in mammary gland or due to microbial action post-milking.

6 Conclusions

GMP is a bioactive peptide with unique chemical properties (glycosylation, absence of aromatic amino acids, self-association, etc.) present in cheese or rennet whey.

Apart from the many biological properties, the peptide has a number of functional properties (emulsification and foaming properties, gel formation) making it an ingredient of choice. Some of the dairy ingredient companies have already realized the potential and is being promoted as a premium ingredient isolated from whey. Potential applications of GMP include its addition in the diet of hepatic and phenylketonuria patients. The addition of GMP to infant formula has been questioned due to its high threonine content (12 to 13 threonine residues) which resulted in higher plasma threonine concentrations (hyperthreoninemia) in GMP containing formula-fed infants vis-à-vis breastfed infants (Rigo et al. 2001). However, later work (Sandström et al. 2008) has not found any such disparity and suggested that the difference in plasma threonine concentrations between formula-fed and breastfed infants could be due to a difference in threonine metabolism. This fact needs to be studied further to arrive at a definite conclusion. The application of GMP as a functional ingredient coupled with its wide pH range solubility and heat stability in specialized products needs to be further explored. However, the high cost of GMP may be a hindrance in its use as a functional ingredient. The research challenge is in its selective isolation from cheese whey on a commercial scale, while keeping the other whey component or protein intact for other uses. Although there are numerous protocols for GMP isolation, there is a tremendous scope to develop simplified and reproducible methods for its large-scale production. The exact reason behind the self-association of GMP at different pH is still required to be investigated thoroughly. GMP as a marker of adulteration of milk with cheese whey has been exploited to a great extent, and almost all of the detection protocols except some chromatographic methods have employed TCA for the removal of interfering κ -CN from milk samples. Among the sensitive immunological techniques, ELISA and Western blot are technically demanding but LFA is convenient. Although the LFA method appears to be promising and it has been commercialized, it inherits the problem of false-positive results like other sensitive methods. The efficacy of these methods also needs to be validated in stored and fermented milk wherein proteolysis may give rise to GMP-like peptides.
